WHAT IS ALREADY KNOWN ABOUT THIS SUBJECT

- Benzodiazepines (BZDs) are not only used as a treatment for anxiety and depression (besides epilepsy), but also inappropriately for chronic insomnia, pain, somatic illnesses [1] and uncontrollable stress.
- In spite of lack of effectiveness and adverse health consequences in chronic BZD use, over 50% are long-term users.
- The relative importance of sociodemographic, psychological and physical determinants of BZD use in general and inappropriate use has never been investigated in a comprehensive, multivariable model.

WHAT THIS STUDY ADDS

- BZDs were used by a considerable proportion of the NESDA participants and BZD use was rarely in accordance with all guidelines, mainly because of an extended duration of use.
- Mentally or physically vulnerable subjects were most likely to use BZDs as well as to use it inappropriately.
- Clinicians should be vigilant when initiating BZD prescriptions for vulnerable subjects, particularly when patients are chronically ill and old, as those subjects are at high risk of inappropriate use.

AIM

Results on determinants of benzodiazepine (BZD) use in general and inappropriate use were inconsistent and mostly univariate. The relative importance of sociodemographic, psychological and physical determinants has never been investigated in a comprehensive, multivariate model.

METHODS

We included 429 BZD users and 2423 non-users from the Netherlands Study of Depression and Anxiety (NESDA) in order to investigate sociodemographic, psychological and physical determinants of BZD use and inappropriate use by logistic and linear regression analyses.

RESULTS

BZDs were used by a considerable proportion of the 2852 NESDA participants (15.0%). BZD use was independently associated with older age, singleness, unemployment, treatment in secondary care, higher medical consumption (more severe) anxiety, depression (OR [95% CI] = 1.95 [1.29, 2.93]), comorbidity, insomnia, SSRI (OR [95% CI] = 2.05 [1.55, 2.70]), TCA and other antidepressant (OR [95% CI] = 2.44 [1.64, 3.62]) use. Overall, BZD use was rarely in accordance with all guidelines, mainly because most users (82.5%) exceeded the recommended duration of safe use. Inappropriate use was independently associated with older age (β = 0.130) and chronic illnesses (β = 0.120). Higher scores on agreeableness were associated with less inappropriate use.

CONCLUSIONS

Mentally or physically vulnerable subjects were most likely to use BZDs. The most vulnerable (i.e. the old and physically ill) BZD users were at highest risk of inappropriate BZD use. Without further evidence of the effectiveness of BZDs in long-term use, caution in initiating BZD prescriptions is recommended, particularly when patients are chronically ill and old, as those are most likely to display inappropriate use.

Introduction

Benzodiazepines (BZDs) are commonly prescribed as a treatment for anxiety and insomnia [2–5]. Remarkably, BZDs are also inappropriately used for pain [6], somatic illnesses [1] and less specific stress responses [7, 8]. Although there is still controversy about the potential for abuse with BZDs, dependence, withdrawal symptoms and side effects, prevalence rates of BZD use are high and vary between 7.5% and 21.3% across countries [9–12]. Due to these high prevalence rates it is informative to obtain a profile of the average BZD user. Specific subject characteristics such as sociodemographic factors (female sex [5, 12–15], older age [3, 5, 12–16], lower education [14], and unemployment [12, 13, 15]), psychological characteristics (worse mental health [3, 13, 15–17], antidepressant use [13, 18], and elevated neuroticism [14, 15, 17]) and physical health factors (chronic illnesses or other physical health problems [1, 13–18], higher medical consumption [18], and pain complaints [6]) were found to be associated with BZD use in previous studies. A number of these variables [5, 12, 13], but not all [14, 15, 17], were identified as important correlates of BZD use in the majority of studies. Several studies did not look at the determinants independently by using a multivariate analysis [3, 5, 14, 17, 18] and no joint investigation of all determinants has been conducted yet.

When BZDs are used as indicated, i.e. at standard therapeutic doses, during a short time period, and only one type of BZD at a time, treatment is usually without strong side effects [19]. Inappropriate BZD use is accompanied by adverse health consequences including cognitive impairment, risk of falling, traffic accidents, and dependence [6, 20–23]. Further, there is little evidence for the effectiveness of BZDs during chronic use [24]. Therefore, several national and international guidelines were formed that, although showing some differences, all recommended a conservative practice of prescription, including short-term use [25–27]. However, more than 20 years after the notion that long-term BZD use should be discouraged, still more than 50% of current BZD users are chronic users (i.e. using BZDs for more than 3 months) [12, 28, 29]. To prevent inappropriate use, it is important to determine which users become inappropriate users. To date, the determinants of inappropriate use have not been investigated. Only the determinants of long-term use have been studied, yet with inconsistent results and without considering the other aspects of inappropriate use (i.e. dosage and number of BZD types used). In those studies, sex [29–31], age [28–33], education [32], psychopathology [32–34], physical health [30, 33, 34], pain complaints [34], daily BZD use [28], use of higher potency BZDs [31] and antidepressants [33] were identified as correlates of long-term BZD use.

To the best of our knowledge, we are the first study to investigate the relative importance of a comprehensive set

of potential determinants of BZD use and inappropriate use in a study among 2852 subjects at various stages of psychopathology participating in the Netherlands Study of Depression and Anxiety (NESDA). We first explored the sociodemographic, psychological and physical correlates of BZD use. Second, we investigated (the determinants of) inappropriate use according to international guidelines [25–27].

Methods

Subjects

Subjects participated in the baseline assessment of the Netherlands Study of Depression and Anxiety (NESDA), an 8-year longitudinal cohort study of 2981 respondents aged 18 to 65 years [35]. NESDA was designed to be representative of individuals with depressive and/or anxiety disorders in different health care settings and developmental stages of illness [35]. Psychiatric status did not seem to be predictive of the initial (non)-response in the NESDA study. (Non)-response was driven by age and sex, i.e. older women more often participated in the NESDA study and young men less often [35]. Subjects were recruited from the community, general practice and specialized mental health care institutions throughout the Netherlands. They completed a medical exam, an in-person interview, and several self-report questionnaires. The study protocol was approved by the Ethics Review Board of each participating centre and all subjects signed an informed consent at the baseline assessment.

We excluded subjects with one or more missing values on BZD use, inappropriate use, sociodemographic, psychological or physical characteristics ($n = 94$). An exception was made for missing values on the Insomnia Rating Scale (IRS) where mean imputation was used due to the high number of missing values ($n = 300$). We also excluded subjects with epilepsy ($n = 29$), as epilepsy is an indication that justifies prolonged BZD use [36].

To obtain an indication of the main determinants of BZD use (aim 1), two groups were defined: subjects who reported BZD use in the month prior to the baseline interview ('BZD users', $n = 429$) and those reporting no use of BZDs in the last month ('non-users', $n = 2423$). For the investigation of adequacy of BZD use (aim 2) only BZD users were considered and further categorized according to adequacy of BZD use.

Benzodiazepine use

Two indicators of BZD use were investigated: BZD use and appropriateness of BZD use.

BZD use during the month prior to baseline interview was registered by observation of drug containers brought to the interview (in 73.4% of cases) or self-report

(in 26.6% of cases). Information was collected about name, dose, number of tablets and duration of BZD use. Medication was coded according to the ATC/DDD (Anatomical Therapeutic Code/Defined Daily Dose) system developed by the World Health Organization (WHO) collaborating Centre for Drug Statistics Methodology. BZDs were classified as ATC-coded groups N05BA, N05CD, N05CG, and N03AE01. The so called 'Z-drugs', of which in the Netherlands only zopiclone and zolpidem (ATC code N05CF) are available, were also included in our analyses, as studies on long-term adverse effects, withdrawal and tolerance development for these drugs are still lacking. The daily BZD dose was computed according to the coding system of the ATC and DDD system [37]. The Mean Daily Dose was calculated by dividing individual daily doses (in mg) of BZDs by the DDD for the particular BZD [38]. For patients using BZDs other than diazepam, an equivalent daily dose was calculated with the conversion tables commonly used by general practitioners' (GPs) [39] and 10 mg diazepam were regarded equivalent to 1 mg alprazolam, 10 mg bromazepam, 0.25 mg brotizolam, 20 mg clobazam, 20 mg chlordiazepoxide, 13.3 mg clorazepate, 8 mg clonazepam, 30 mg flurazepam, 1 mg loprazolam, 2 mg lorazepam, 1 mg lormetazepam, 7.5 mg midazolam, 10 mg nitrazepam, 33 mg oxazepam, 20 mg prazepam, 20 mg temazepam, 20 mg zolpidem and 13 mg zopiclone. Dosages were summed when more than one BZD was used. Types of BZDs were subdivided into short acting ($t_{1/2} < 24$ h) and long acting ($t_{1/2} \geq 24$ h) BZDs. Duration of use was categorized as short-term (≤ 3 months) or long-term (> 3 months). The number of different types of BZDs used was categorized into 1, 2, or 3. BZDs were further divided into anxiolytics (ATC code N05BA, $n = 263$) and hypnotics (ATC codes N05CD and N05CF, $n = 147$).

Appropriateness of use was based on the Dutch practice guidelines for anxiety and insomnia [26, 27] and the British National Institute of Health and Clinical Excellence treatment guidelines for general practitioners [25]. The following criteria for appropriate use were derived:

- 1 mean daily dosage \leq DDD as defined by the World Health Organization.
- 2 duration of benzodiazepine use ≤ 3 months in case of no concomitant antidepressant (AD) use and ≤ 2 months in case of concomitant AD use.
- 3 only one type of BZDs is used at a time.

Based on the number of appropriate criteria not met by a subject, an inappropriateness score (range 0–3) was calculated. An inappropriateness score of 0 indicated that a subject met all three appropriateness criteria (i.e. appropriate use) whereas an inappropriateness score of 3 indicated that none of the appropriateness criteria was met (i.e. highly inappropriate use).

Demographic, psychological and physical characteristics

Based on previous studies, various potential determinants of BZD use and adequacy of BZD use were included and grouped into sociodemographic characteristics (age, gender, education, marital status and work status), psychological characteristics (current psychopathology, health care setting, severity of anxiety or depression symptoms; insomnia; antidepressant use, and personality traits) and physical characteristics (number of chronic diseases, medical consumption, pain complaints and smoking) [5, 12–15, 29, 32–34, 40].

Sociodemographic characteristics Gender, age, education level (in years), work status (employed vs. unemployed), and partner status (living with partner vs. single) were reported in the baseline interview.

Psychological characteristics In NESDA, depressive (dysthymia or Major Depressive Disorder, MDD) and anxiety (panic disorder with or without agoraphobia, generalized anxiety disorder or social phobia) diagnoses were measured by the Composite International Diagnostic Interview (CIDI, life time version 2.1), which classifies diagnoses according to the DSM-IV criteria. Current diagnoses were defined as those in the last year. The severity of generalized anxiety and panic symptoms were assessed with the Beck Anxiety Inventory (BAI) [41]. The presence of insomnia was determined using the Insomnia Rating Scale (IRS) [42]. The severity of depressive symptoms was measured by the cognitive/mood scale of the Inventory of Depressive Symptomatology Self Report (IDS-SR) [43]. In order to avoid overlap with the BAI and IRS, we did not include the anxiety/arousal and sleep scales of the IDS-SR. So as to make the score of BAI, IDS-SR and IRS comparable, z-scores were calculated and z transformed values were used for regression analyses. Personality traits were assessed with the Neuroticism Extraversion Openness-Five Factor Inventory (NEO-FFI), a 60-item questionnaire measuring five personality domains: neuroticism, extraversion, agreeableness, conscientiousness and openness to experience [44]. Antidepressant use was reported during the interview. The ATC-coded groups N06AA, N06AB, N06AF, N06AX and N06AG were classified as antidepressants.

Physical characteristics An inventory of somatic diseases was made by detailed questions of the presence of the following chronic illnesses: chronic lung disease, heart condition, diabetes mellitus, stroke, arthritis, rheumatism, cancer, hypertension, ulcer, intestinal problems, liver disease, chronic fatigue syndrome, allergy, thyroid gland, head injury or other injuries. Based on the number of chronic diseases a subject suffered from, a score ranging from 0 to 17 was calculated. Medical consumption was defined as the number of GP consultations in the 6 months prior to the interview, as assessed with the Perceived Need

BAI indicates Beck's anxiety index; IDS-SR indicates Inventory of Depressive Symptomatology; IRS indicates insomnia rating scale; MDD indicates major depressive disorder; SSRI indicates selective serotonin re-uptake inhibitor; TCA indicates tricyclic antidepressant. Means (95% confidence intervals) are given for age, chronic illnesses, pain and personality traits. Medians (interquartile range) are given for education level, medical consumption IRS, BAI and IDS as these values are not normally distributed. Percentages are given for categorical variables. *P* is derived by analysis of variance (ANOVA) for quantitative, normally distributed variables, Mann–Whitney *U*-test for continuous, non-normally distributed variables or χ^2 statistics for categorical variables. Significance is inferred at *P* < 0.10.

for Care Questionnaire (PNCQ) [45]. Pain complaints were measured with the Chronic Graded Pain Scale and pain severity (consisting of pain intensity and disability) was summarized by the Chronic Pain Grade according to Korff *et al.*, which is a score ranging from 0 to 4 [46]. Smoking was reported during the interview.

Statistical analyses

Sample characteristics and characteristics of BZD use were expressed by frequencies, means or medians, and compared using χ^2 statistics (for categorical variables), analysis of variance (ANOVA, for normally distributed, continuous variables), and Mann–Whitney *U*-test (for non-normally distributed, continuous variables). Non-normally distributed values were naturally log transformed for regression analyses.

Univariate logistic and linear regression analyses were carried out to identify correlates of BZD use (vs. non-use as the reference category) and inappropriate use (appropriateness score ranging from 0–3). Odds ratios with 95%

confidence intervals (OR [95% CI]) and standardized betas (β) were provided as outcome measures. All independent variables with *P* < 0.10 in univariate analyses were entered in the multivariate regression models. The *P* value was set at *P* < 0.10 (instead of *P* < 0.05) in order to avoid missing important determinants of BZD use that do not reach significance in univariate analysis at *P* < 0.05 but will when correcting for possible confounders in multivariate analyses. The following variables were considered: (1) demographic variables: gender, age, education level, work status, and marital status; (2) psychological characteristics: current psychopathology, health care setting, severity of anxiety and depression symptoms, insomnia, antidepressant use and personality traits; and (3) physical characteristics: number of chronic diseases, medical consumption, pain complaints and smoking. The analysis was adjusted for sex and age. Significance in the multivariate model was inferred at *P* < 0.05.

Finally, we compared anxiolytic and hypnotic users on possible characteristics of BZD use using χ^2 statistics

(for categorical variables), ANOVA (for normally distributed, continuous variables), and Mann–Whitney *U*-test (for non-normally distributed, continuous variables) to find out whether there would be group differences. Significance was inferred at $P < 0.05$. All analyses were conducted with SPSS 16.0 for Windows.

Results

BZD use

Of the 2852 subjects, 429 (15.0%) had used a BZD in the past month. Table 1 shows the sociodemographic, psychological and physical characteristics of BZD users as compared with non-users.

BZD users were older (mean 46.3 vs. 41.2 years, $P < 0.001$), more likely to be single (36.4% vs. 29.6%, $P = 0.005$) and more likely to be unemployed (51.7% vs. 28.4%, $P < 0.001$). Further, BZD users displayed worse physical (3.0 vs. 2.0 medical consumption, $P < 0.001$) and psychological health (BAI score of mean 20.0 vs. 8.0, respectively, $P < 0.001$).

Table 2 shows the effect of putative correlates of BZD use as opposed to non-use among all subjects. Univariate *P* values of these analyses are shown in Table 1 which comprises group comparisons conducted with ANOVAs. An ANOVA results in exactly the same *P* value as a regression analysis.

In multivariate analyses, the following variables were significant correlates of BZD use: older age (OR = 1.48), singleness (OR = 1.34), unemployment (OR = 1.56), treatment in secondary care (OR = 1.55), higher medical consumption (OR = 1.41), a diagnosis of depression (OR = 1.56), anxiety (OR = 1.95) and comorbidity (OR = 1.78), higher scores on the IRS (OR = 1.35) and BAI (OR = 1.65) questionnaires, use of SSRIs (OR = 2.05), TCAs (OR = 1.84) and other antidepressants (OR = 2.44).

In the comparison between anxiolytic and hypnotic users, groups were similar on most variables, except of the following: Anxiolytic users were younger (45.3 vs. 47.8, $P = 0.04$), had more often a diagnosis of anxiety (25.2 vs. 14.9%, $P = 0.02$), less often a diagnosis of depression (15.9 vs. 28.9%, $P = 0.009$), had lower scores on insomnia

Table 2

Determinants of benzodiazepine use as opposed to non-use: results from univariate and multivariate logistic regression analyses ($n = 2852$)

BAI indicates Beck's anxiety index; IDS indicates Inventory of Depressive Symptomatology; IRS indicates insomnia rating scale; MDD indicates major depressive disorder; SSRI indicates selective serotonin re-uptake inhibitor; TCA indicates tricyclic antidepressant. Significance is inferred at $P < 0.10$. *The *P* values were obtained by univariate analyses. **The *P* values were obtained by multivariate analyses.

(9.0 vs. 13.0, $P \leq 0.001$) and higher scores on agreeableness (31.8 vs. 30.5, $P = 0.02$, data not shown).

Appropriateness of BZD use

In Table 3, we present the characteristics of BZD use among the 429 BZD users. The median daily dosage used was 2.5 mg of diazepam equivalents (interquartile range [IQR] 0.7–6.0) and the median duration of BZD use was 24 months (IQR 5.0–84.0). The most frequently used BZD was oxazepam (44.3%), followed by temazepam (14.9%), diazepam (14.7%) and alprazolam (6.1%).

Only 17.5% of all BZD users took BZDs for the appropriate duration of 3 months whereas 82.5% of users took BZDs for a much longer period. The remaining appropriateness criteria were met more frequently. The majority of the BZD users (86.0%) did not exceed the recommended DDD as defined by the WHO and 84.4% of users had only a prescription for one type of BZD at a time. However, mainly due to the high duration of BZD use of most users, only 15.2% of BZD users met all three appropriateness criteria, whereas 64.3% met two criteria, 13.8% met one and 6.8% of users did not meet any criterion (highly inappropriate use).

Table 4 shows the effect of potential correlates of inappropriate BZD use among all BZD users. Age ($\beta = 0.130$) and

chronic illnesses ($\beta = 0.120$) were significantly associated with higher inappropriate BZD use. Higher scores on agreeableness were associated with lower inappropriate use ($\beta = -0.111$).

Discussion

BZDs were used by a considerable proportion of the 2852 NESDA participants (15.0%). BZD use was independently associated with older age, singleness, unemployment, treatment in secondary care, high medical consumption (more severe) anxiety, depression, comorbidity (more severe) insomnia and antidepressant use. Inappropriate BZD use was independently associated with older age and chronic illnesses. High scores on agreeableness were correlates of less inappropriate use. Overall, BZD use was rarely in accordance with all guidelines, mainly because most users (82.5%) exceeded the recommended maximum duration for safe use.

Although the uncritical enthusiasm about BZD use has been over for many decades [30, 47, 48], BZDs are still not only used for the treatment of severe insomnia and anxiety (other than epilepsy), but also to alleviate stress caused by adverse life circumstances such as unemployment [49] as well as pain [6] and other somatic complaints [1]. Largely corresponding to earlier findings, our results show that mainly the physically and mentally more vulnerable, e.g. the old [5, 13, 29], unemployed [12, 13, 15], psychologically [3, 13, 15–17, 32–34] and physically [14, 18, 34] ill subjects are using BZDs and use these BZDs inappropriately. There seems to be a tendency from relatively non-vulnerable subjects being non-users, mildly vulnerable being users and highly vulnerable being inappropriate users. Consistently, vulnerable subjects reported lower perceived support [50–52] as well as more maladaptive coping strategies [18, 32, 50, 51, 53] and were found to display more emotional arousal when facing stressful events as compared with less vulnerable subjects [49]. They might substitute those deficits with BZDs [49, 52] and be more likely to ask their medical doctors (MDs) for tranquillizers to alleviate their distress. MDs themselves might also be more likely to prescribe BZDs to vulnerable subjects as compared with all other problems these people have due to unemployment, chronic illnesses and psychopathology, BZD use seems to be the least concerning issue. A number of qualitative research studies investigated the prescription habits of MDs and found that the majority of questioned MDs were aware of the guidelines [54, 55] and supported conservative prescription practice of BZDs [54]. A reported reason for prescribing nonetheless was feeling poorly equipped to solve the emotional problems of their troubled patients [56], but wanting to alleviate their distress [55] and maintain a good doctor-patient relationship [54, 55]. If MDs received more (psychological) education on how to communicate their reasons for declining

Table 3
Characteristics and adequacy of benzodiazepine (BZD) use ($n = 429$)

Benzodiazepine use	
Type of BZD	
Short acting (%; $t_{1/2} < 24$ h)	81.1
Long acting (%; $t_{1/2} \geq 24$ h)	18.9
Mean daily dose (mg day ⁻¹)†	2.5 (0.7–6.0)
Duration of use (months)	24.0 (5.0–84.0)
Daily BZD use (%)	38.5
Number of different types of BZDs used concomitantly (%)	
1	84.4
2	14.0
3	1.6
Most frequently used BZDs (%)	
Oxazepam	44.3
Temazepam	14.9
Diazepam	14.7
Alprazolam	6.1
Lorazepam	4.2
Zopiclone	3.7
Adequate BZD use	
Mean Daily Dose/DDD‡ ≤ 1 (%)	86.0
Duration of use ≤ 3 months (%)	17.5
Use of only 1 type of BZD (%)	84.4
Inadequacy score§ (%)	
0	15.2
1	64.3
2	13.8
3	6.8

†Expressed as diazepam equivalents, ‡DDD indicates defined daily dose (DDD for diazepam: 10 mg day⁻¹), §an inadequacy score of 0 indicates that all adequacy criteria are met (adequate use), an inadequacy score of 3 indicates that none of the criteria is met (inappropriate use). Median (interquartile range) is given for mean daily dose and duration of use. Percentages are given for categorical variables.

Table 4Determinants of inappropriate† benzodiazepine (BZD) use: results from univariate and multivariate linear regression analyses (*n* = 429)

	Univariate analysis β	<i>P</i> value	Multivariate analysis β	<i>P</i> value
Sociodemographics				
Sex (female)	−0.003	0.96	0.018	0.72
Age (years)	0.153	0.001	0.130	0.008
Marital status (single)	0.065	0.18		
Employment status (not working)	0.114	0.02	0.073	0.14
Education level (years)	−0.078	0.11		
Health care setting (secondary care)	0.010	0.84		
Physical health				
Medical consumption	−0.043	0.37		
Chronic illnesses	0.173	<0.001	0.120	0.02
Pain	0.078	0.11		
Smoking	−0.034	0.48		
Psychological characteristics				
Current diagnosis (%)				
MDD only	−0.067	0.16		
Anxiety only	−0.028	0.56		
Comorbid disorder	0.060	0.21		
IRS	0.013	0.79		
BAI	0.075	0.12		
IDS-SR mood/cognition scale	0.076	0.12		
Personality characteristics				
Neuroticism	0.008	0.87		
Extraversion	−0.113	0.02	−0.043	0.40
Openness	−0.098	0.04	−0.065	0.18
Agreeableness	−0.126	0.009	−0.111	0.03
Conscientiousness	−0.017	0.73		

BAI indicates Beck's anxiety index; IDS-SR indicates Inventory of Depressive Symptomatology Self Report; IRS indicates insomnia rating scale; MDD indicates major depressive disorder; SSRI indicates selective serotonin re-uptake inhibitor; TCA indicates tricyclic antidepressant. †Inappropriate BZD use is calculated with an inadequacy score. An inadequacy score of 0 indicates that all adequacy criteria are met, an inadequacy score of 3 indicates that none of the criteria is met. Significance is inferred at *P* < 0.10.

prescriptions to the patients, they might prescribe less and initiate BZD discontinuation more often [54, 56, 57].

As could be expected, anxiolytic BZDs were more often used in cases of anxiety disorders and hypnotic BZDs more often in cases of insomnia. However, it also seems that the drugs are insufficient to provide therapeutic relief as otherwise lower anxiety and insomnia scores were to be expected in the respective groups. Group differences on age and agreeableness were unexpected and difficult to explain.

In general, the high percentage of inappropriate users in NESDA is disconcerting. The majority (84.8%) of users did not use BZDs according to international guidelines [25–27], mainly due to exceeding the maximum duration of recommended use. This is striking considering that for more than 20 years BZDs have been known to cause side effects and dependence and evidence for the drug's effectiveness in long-term use is controversial [7, 8]. In addition, several NESDA subjects surpassed the recommended daily dosage (14.0%) and used more than one type of BZD concomitantly (15.6%). Dosage escalation is generally unsafe, as side effects become more pronounced and can have adverse consequences ranging from low performance at work to falls and traffic accidents [6, 20–22]. BZDs should be reserved for the severely anxious who have tried AD

medication with no effect and have BZDs as a last treatment option. However, BZD prescriptions cannot be discontinued without providing patients with alternative coping strategies. Training should be conducted to strengthen BZD users' coping skills [11, 58], self-efficacy and positive outcome expectations [11] and to lessen their disengagement beliefs [11] as such efforts may increase the chance of successful BZD discontinuation [11, 58]. In spite of all objections and in view of the restricted financial resources in the health sector, it is clear that prescribing BZDs takes less time than providing psychological support [7, 55]. Therefore, BZD use should be targeted with relatively quick and cheap methods that have been developed (e.g. computer-tailored education [11], discontinuation letters [59]) and have been found to increase effectively BZD cessation rates [11, 59].

The present study has some limitations. The cross-sectional design does not allow us to make causal inferences on whether determinants preceded BZD use or *vice versa*. Although participants were asked to bring drug containers to the interview, one fourth of the subjects did not adhere to that and reported medication use from memory leading to a potential recall bias. The 84.8% inappropriate user number is probably an overestimation, as long-term users were more likely to be included in the user group

than short-term users due to the cross-sectional design. A strong aspect of our study is the conductance of a multivariate analysis across a comprehensive set of possible determinants of BZD use. Furthermore, we included all aspects of inappropriate BZD use in a large sample composed of subjects with a range of psychopathology.

In conclusion, this study revealed three major points: (1) the vast majority of NESDA subjects displayed inappropriate BZD use, mainly due to exceeding the maximum duration of recommended use; (2) it is primarily the physically or mentally vulnerable subjects who use BZDs; and (3) the most physically ill of the BZD users are at highest risk for inappropriate use. Without further evidence for the effectiveness of BZDs in long-term use, caution in initiating BZD prescriptions is recommended, particularly when patients are chronically ill and old, as these subjects are most likely to display inappropriate use.

Competing Interests

There are no competing interests to declare.

The infrastructure for the NESDA study (<http://www.nesda.nl>) is funded through the Geestkracht program of the Netherlands Organisation for Health Research and Development (ZonMw, grant number 10-000-1002) and is supported by participating universities and mental health care organizations (VU University Medical Center, GGZ inGeest, Arkin, Leiden University Medical Center, GGZ Rivierduinen, University Medical Center Groningen, Lentis, GGZ Friesland, GGZ Drenthe, Scientific Institute for Quality of Health Care (IQ Healthcare), Netherlands Institute for Health Services Research (NIVEL) and Netherlands Institute of Mental Health and Addiction (Trimbos).
